Abstract

The present work is a continuation of research on alloys based on iron, aiming at understanding the solidification behaviour of Fe-Cr-Nb alloys. Ternary Fe-Cr-Nb alloys with different concentrations were arc-melted and systematically characterized by means of: differential thermal analysis, optical and scanning electron microscopy coupled to an energy dispersive X-ray microprobe analysis and X-ray diffraction.

For the first time, we suspect the presence of a metastable α’-phase in Fe-rich alloy. For higher vanadium and niobium contents a competition between two eutectics, E2 and E3, is clearly shown according to the observed microstructures and the solidification sequences.

Keywords:
Ternary diagram, Phase Equilibrium, differential thermal analysis, phase transition, solidification sequences.

1 INTRODUCTION

Recent years have witnessed a growing demand for structural materials capable of withstand oxidizing environments at high temperatures in various areas, including aviation turbine. These materials must have, besides an excellent resistance to oxidation at high temperature, high melting point and mechanical properties depending on temperature control [1, 2].

To overcome these limitations and further performance, the use of intermetallics could open new avenues to exploit appropriate combinations.

New systems of intermetallic compounds with more complex structures and melting points are higher ups guidance for developing new material systems.

In the present work, the thermal and microstructural behavior of Fe-Cr-Nb alloys in the Fe-rich corner have been studied aiming at paying attention to the equilibrium intermetallic phases, the distribution of phases, their morphology and microstructures. The major difficulty in this work is to explain the microstructures observed considering the recorded thermograms.

Also, Note that the elements Fe, Cr and Nb have attractive properties in points of view of stability at high temperature, mechanical properties and resistance to the environment [3-6].

EXPERIMENTAL

Series of ternary iron-chromium-niobium alloys were prepared using pure iron of 99.99% purity and pure chromium and niobium of 99.9% purity. The stoichiometric mixtures of iron, chromium and niobium were arc melted (Buhler MAM1 furnace type) several times (minimum 4 times), to ensure the homogeneity of our samples, in a pure argon gas atmosphere (5N) in a water-cooled copper crucible.

Differential thermal analysis (DTA) specimens cut as small cylinders with φ = 4 mm × 10 mm in length (1 g maximum) were prepared from the alloys, and a Netzsch 404 S DTA apparatus was used for the thermal analysis.

DTA measurements were taken in the cooling regime. The specimens were heated at 10 K.min⁻¹, up to a maximum temperature of 1550 °C, and cooled (at 10 K.min⁻¹) to room temperature. The heating and cooling were in an argon (5N) flow gas atmosphere (150 ml.min⁻¹) to prevent samples from oxidation. The temperature was measured using a type S thermocouple and Al₂O₃ powder was used as the reference.

Ingots were cut, polished and observed by optical and scanning electron microscopy (SEM). The microstructures of the alloys were checked using a Zeiss ICM 405 optical microscope and a Jeol JSM 6360LV scanning electron microscope. The composition (semi-quantitative) of the phases was identified by means of Energy Dispersive X-Ray Spectrometry (EDS) analysis. The EDS analysis of different phases was performed under controlled conditions (counts.s⁻¹ and size of phases) in order to be able to compare the results from different specimens. Prior to microscopic observations, samples were treated with nital solution (3 ml of HNO₃ in 100 ml of ethanol) for 30 s at room temperature.

For phase identification and crystallinity analysis, X-ray diffraction (XRD) experiments were carried out using a Philips PW1730 diffractometer and a scanning rate of 0.004°s⁻¹ over the range 2θ = 20–140°, with unfiltered Cu-Kα radiation (λ = 1.5406 Å), operating at 45 kV and 45 mA.

3 RESULTS AND DISCUSSION

Table 1 shows the alloy compositions, the transformation temperatures and the solidification sequences in relation with the observed microstructures. The α-solid solution is identified as the primary crystallisation phase (EDS 1, Fig.1b and Fig.4b) in all studied compositions.

The DTA results and the microscopic observations allow us to distinguish three FeCrNb alloys families.
3.1 Alloy 1

The microstructure (Fig. 1) shows α(Fe) dendritic structure. The interdendritic space in this case remains rather limited. The microstructure (Fig. 1b) observed at large magnification, is characteristic of the homogeneous matrix composed primarily of iron admixed a low substitution of chromium and niobium. This is probably a solid solution α(Fe-Cr) as predicted by the binary Fe-Cr phase diagram [7]. Chemical analysis by means of EDS of the interdendritic space (clear phase) shows a biphasic structure formed from α(Fe) and a very fine iron-based phase which is Nb-rich. The thermogram of the alloy 1 (Fig. 2) shows four peaks at 1410°C, 1290°C, 835°C and 777°C.

These temperatures are attributed respectively to the transformations: formation of primary dendrites (L ↔ α), rearrangement of part of the primary phase α to α' (α ↔ α’) [8], solidification of the interdendritic liquid showing a globular aspect (eutectic E1 transformation) and occurring of the magnetic transformation.

Note that the shape of the second (1290°C) and last (777°C) peak reflect the presence of second order transformations (α→α’ transformation and magnetic). However, the low intensity of the third peak at 835°C (Fig. 2) is related to the low percentage of interdendritic space (Fig. 1).

Figure 1: Alloy 1 SEM microstructure, EDS spectrum semi-quantitative analysis from:
(1) Gray area, (2) Clear area.
3.2 Alloy 2

The DTA curve obtained for the alloy 2 (Fig. 3) reveals the presence of four exothermic peaks at 1390°C, 1345°C, 1310°C and 750°C. Correlated with the conclusions made on the crystallization of the sample 1, we suggest that the first peak (1390°C) correspond to the solidification of the primary phase (L→α), the third (1310°C) to the α → α' transformation, and finally the last peak (750°C) to the magnetic transformation.

Note, that the shape of the second peak raised to 1345 °C and that it is not detected in Sample 1. This reflects the occurrence of a new transformation.

The microstructure of this alloy (Fig. 4b) confirms this assumption: it reveals dendrites (dark 1) and an eutectic structure (clear 2) located in the interdendritic space. According to the matrix chemical analysis (Fig. 4b, EDS1) we identified this phase to the α-solid solution (Fe-Cr)

The interdendritic space (Fig. 4b, EDS2) shows a biphasic structure formed from a dark contrast with a chemical composition close to the α one, and a clear contrast which we could assign to the crystallization of an iron-chromium-niobium phase. The interdendritic space in this case corresponds to almost 40% vol. of the amount of the sample.

According to our experimental results (the important size of second DTA peak associated to the SEM interdendritic microstructure which reveals a biphasic structure, the second DTA peak may be associated with the crystallization of an eutectic α/pseudo-binary phase) or (α/ternary Fe-Cr-Nb phase), denoted E2.

Figure 3: DTA curve of the alloy 2 on cooling with a heating rate of 10 K.min⁻¹, showing four peaks at 1390°C, 1345°C, 1310°C and 750°C.
3.3 Alloy 3 and 4

Alloy 3 and alloy 4 exhibit the same behavior, so only results concerning the alloy 4 will be presented in this paper.

The DTA curve obtained for alloy 4 (fig. 5) reveals the presence of three exothermic peaks at 1405 °C, 1390 °C and 1340 °C. The examination of solidification sequences and the microscopic observations (fig.6) allow us to suggest that these peaks correspond respectively to the reactions: \( \text{L} \leftrightarrow \alpha \) (Fe-Cr), followed by the formation of a eutectic \( \text{E3} \) at 1390 °C, and eutectic \( \text{E2} \): \( \alpha \) + pseudo-binary or ternary Fe-Cr-Nb phase at 1340 °C. However, we note the absence of the magnetic transition in this composition range.

The microstructure of this alloy (Fig. 6a) reveals the presence of two eutectics:

- The eutectic \( \text{E2} \) characterized by a lamellar morphology. The chemical analysis of white phase (EDS 1, Fig. 6b) reveals a composition of approximately 40% iron-chromium and 60% niobium, which correspond to the pseudobinary \( \text{Nb}_{19}(\text{FeCr})_{21} \) phase [7]. According to this result, we identified this \( \text{E2} \) eutectic to the \( \alpha \)-solid solution (matrix) and variable stoichiometry of the pseudo-binary \( (\text{FeCr})_{x}\text{Nb}_{y} \) phase.

- The second eutectic denoted \( \text{E3} \), reveals the existence of two-phases precipitates in the matrix \( \alpha \). The first phase rich in niobium (EDS 1, Fig. 6d) could be assigned to the crystallization of the \( \text{Nb(FeCr)} \) phase. The second phase (in the center), rich in iron (EDS 2, Fig. 6d) could correspond to the formation of a pseudo-binary phase \( (\text{Fe-Cr})_{x}\text{Nb} \).

Figure 5: DTA curve of the alloy 4 on cooling, with a heating rate of 10 K.min\(^{-1}\).
Figure 6: Alloy 4 SEM microstructure, EDS spectrum and semi-quantitative analysis from:
1) White area,
2) Light gray area.
3.4 phase identification by XRD
The superposition of the spectrum of X-ray diffraction of the four alloys (Fig.7) indicates the presence of the \( \alpha \)-solid solution, and confirms the enrichment of chromium in the matrix (table 1, from alloy 1 to alloy 4) by the shift of the peaks characteristic of the ferritic phase to the upper angle. This feature is due to chromium atomic radius smaller than that of iron and the presence of very small amount of niobium in the sample 1.

The presence of the \( \alpha' \)-phase is not confirmed by the X-ray analysis diffraction in alloy 1 and 2 (Fig.7a, Fig.7b). The pattern of these alloys exhibits only the \( \alpha \)-solid solution. The two phases \( \alpha \) and \( \alpha' \) crystallize in the same crystalline structure (centered cubic) type CsCl with lattice parameter very close, and therefore the choice of X-radiation, Co-K\( \alpha \) or Cu-K\( \alpha \), would not distinguish \( \alpha \) from \( \alpha' \). In our work conditions (Cu-K\( \alpha \)), it is impossible to distinguish between \( \alpha \) and \( \alpha' \). However, Samples 3 and 4 (Fig.7c, Fig.7d) indicate also the presence of the \((FeCr)_{2}Nb\) phase.

4. CONCLUSIONS
The phase diagram of Fe-Cr-Nb compounds in the Fe rich region is investigated using DTA analysis, metallographic and X-ray diffraction. Some changes were observed and Based on the experimental results, the following conclusions can be made:

- The results obtained confirm that the \( \alpha-(Fe-Cr) \) solid solution, is the primary crystallization phase in all compositions shown in Table 1.
- According to the DTA results, the separation of the \( \alpha \)-solid solution in alloy 1 and 2 is suspected [9]. The phase transition \( \alpha \)-solid solution\( \rightarrow \)metastable \( \alpha' \)-phase is seen in the temperature range between the magnetic transition and the \( \alpha \)-solid solution crystallization.
- The occurrence of two eutectics, E2 and E3, in equilibrium in alloys 3 and 4 is observed. The competition between these eutectics, is seen for a higher composition ranging from 17 to 23 at.% Cr and 7 to 8 at.% Nb.
